Ásványtani mozaikok a Kárpát–Pannon régióból 2.

Összefoglalás

Tanulmányunkban további mozaikszerű információkat közzünk a Kárpát–Pannon régió új ásványtani eredményeiből. Az adatokat országok és lelőhelyek szerint csoportosítottuk. Az egyes „mozaikdarabokban” az ásványok pontos — döntően XRPD, SEM-EDX és EMPA általi — meghatározására, illetve a paragenetisztikai tömör bemutatására koncentráltunk. A tanulmányunkban szereplő ásványok olykor első említések az egész régióból, vagy legalábbis az illető lelőhelyről.

Magyarországról a recski rézércesedés mélyszintjéről néhány Bi-szulfidot (bizmutin, galenobizmutit), a recens hidrotermás kiválásokból pedig réz-kloridotokat (erioalkit, atacamit) mutattunk be. A pátkai polimetallikus-fluoritos ércsedésből wulfenitet, míg egy bátonyterenyei széntelepből a benyomuló bazalttérek hatására képződött phillipsit-Na-t ismertetünk.

Romániából másodlagos Bi-ásványokat (bizmutit, bizmutoferrit) dokumentáltunk műszeres vizsgálatokkal Vaskőről (Ocna de Fier). Brianyoungitot mutattunk ki a nagyági (Săcărâmb) bánya meddőhányójáról, illetve spertiiniitet a rézbányai (Băița [Bihor]) szkarnos polimetallikus ércsedésből. Rögzítettük a konyait előfordulását a Nagysármás (Şarmașu) melletti szikes kivirágzások között.

Szlovákiából amarantitot és butleritet azonosítottunk a szomolnoki (Smolník) ércsedésből, richelsdorfitot Iglo-hutáról (Novoveská Huta). Végül egy sor járulékos szulfátásványt (hexahidrit, epsomit, thénardit, glauberit, konyait, eugsterit, blödit) mutattunk ki a gömörhorkai (Gemerská Hôrka) gipsz-anhidrit telepből.

Tárgyszavak: galenobizmutit, atacamit, erioalkit, wulfenit, phillipsit-Na, bizmutoferrit, bizmutit, spertiiniit, konyait, brianyoungit, amarantit, butlerit, richelsdorfit, blödit, hexahidrit, thénardit, epsomit, glauberit, eugsterit

Abstract

This paper focuses on the compilation of new, mosaic-like mineralogical data from the Carpathian–Pannonian region. The data are grouped into entries arranged by localities and countries. Individual entries are linked to the exact identification of a species (or some species). These are dominantly based on XRPD, EMPA and SEM-EDX data, and are completed by the description of its/their paragenesis. The details presented here contain either the first description of a species from the whole region or at least from the given locality.

1) Hungary. Two Bi-sulphide minerals (bismuthinite, galenobismutite) are reported here from the deep levels of the Recsk copper deposit, together with the description of two copper chloride species (eriochalcite, atacamite) deposited by recent hydrothermal fluids. Wulfenite from the polymetallic–fluorite-type mineralisation of Pátka (in the Velence Hills) is also presented. The last entry is phillipsite-Na from Bátonytereny, where the mineral was formed by the effect of basalt veins penetrating the coal seams.

2) Romania. Secondary Bi-minerals (bismutite, bismutoferrite) are documented from Ocna de Fier (Vaskő), Banat. Brianyoungite is described from the waste material of the Săcărâmb (Nagyág) mine, and also spertiiniite from the polymetallic mineralisation of Băița Bihor (Rézbánya). Konyaite was found in alkaline salt efflorescences near Sărmașu (Nagysármás).

3) Slovakia. Amarantite and butlerite from the pyrite-rich mineralisation of Smolník (Szomolnok), and richelsdorfit from the copper ore deposit Novoveská Huta (Iglóhuta), were identified. Numerous sulphate minerals (hexahydrite, epsomite, thénardite, glauberite, konyaite, eugsterite, blödite) are described from the gypsum-anhydrite deposit of Gemerská Hôrka (Gömörhorka).

Keywords: galenobismutite, atacamite, eriochalcite, wulfenite, phillipsite-Na, bismutoferrite, bismutite, spertiiniite, konyaite, brianyoungite, amarantite, butlerite, richelsdorfit, blödite, hexahydrite, thénardite, epsomite, glauberite, eugsterite

Experimental methods

X-ray powder diffraction patterns were recorded on a Bruker D8 Advance diffractometer using CuK α radiation (40 kV and 40 mA). This also involved a 250 mm radius goniometer, with parallel-beam geometry obtained by Goebel-mirror optics, a 0.25° primary axial Soller with a 0.6-mm divergence slit, and a 0.12° detector side long-Soller. 1 to 5 mg samples were ground in agate mortar under acetone and loaded on Si single-crystal sample holders. All measurements were recorded in the 2–70° (2 θ) range with a 0.01° (2 θ) / 2 sec scanning rate.

X-ray diffraction measurements were also performed with a 114.6-mm diameter Gandolfi camera. Analytical parameters: CuK α radiation, Ni filter, 40 kV accelerating voltage, 20–25 mA tube current, exposition time: 44 to 46 hours. Unit cell parameters were calculated with the Unit-Cell software (HOLLAND & REDFERN 1997). NIST SRM 640 silicon powder was used as the external standard for the correction of film shrinkage.

Scanning electron microscopy (SEM) studies, energy-dispersive X-ray spectroscopy (EDX), EDX mapping and electron microprobe measurements (EMPA), were done on a JEOL–JXA 8600 Superprobe unit equipped with four wavelength-dispersive spectrometers and an E2V Scientific Instruments EDX silicon drift detector (SDD). For the EDX measurements 15–20 kV acceleration was used, with a probe current of 10–20 nA. A 4×5 μm area was scanned with a focused beam during the analyses (a stopped focused beam was used if the target area was too small).

Results

Hungary

Bismuth sulphides from the deep levels of the Recsk ore deposit

Bismuth-containing sulphides were first mentioned from Recsk (Lahóca deposit) by SZTRÓKAY (1944), based on his ore-microscopy investigations. He assumed the presence of galenobismutite in the enargite-dominant ores. Later, Pb-Bi-sulphides were found by microprobe in the enargite-luzonite mineralisation of the Rm-48 inclined adit (“Lejtakna” deposit) (DOBOSI 1971, BAKSA 1975). These Pb-Bi sulphides formed inclusions in enargite and luzonite. In 1987–88 Gábor PAPP (then Department of Mineralogy, Eötvös Lorand University, Budapest, personal communication) studied bismuthinite from a similar paragenesis of the deep levels of the Recsk deposit. According to the X-ray spectroscopy (XRS) results the mineral contained a considerable amount of Se. In the 80s Gábor DOBOSI (then Geochemical Research Laboratory of the Hungarian Academy of Sciences) found 1.1–1.4 wt% Se by microprobe analysis in the small (< 30 μm) grains. An XRS analysis of the acicular stibnite inclusions in calcite was also made in 1988 but did not reveal any trace elements.

Higher amounts of Bi-containing sulphides were found in the exoskarn ores explored by the West 3rd adit on the –900 m level. They are enclosed in coarse crystalline calcite associated with serpentine minerals, talc and chlorite and subordinate anhydrite and fluorite are also present. Calcite is frequently dark grey due to the dense, hair-like sulphide inclusions. The needle-like inclusions frequently form patches of 1–2 mm in diameter, while the felt-like aggregates can reach 1 cm in size. These aggregates are mainly built up of bismuthinite and galenobismutite (Figure 1). 1–3 wt% lead (Pb) is always present in bismuthinite, while the

chemical composition of galenobismutite is close to the ideal formula (Tables I–II). Both sulphides were identified by XRPD. The observed characteristic reflections of galenobismutite were: 3.45 Å (3.47 Å), 3.41 Å (3.45 Å), 2.05 Å (2.05 Å) — (data of ICDD card 20-0571 are in brackets). Some unique 1–3 μm size “flakes” were found by micro-

probe with compositions close to tetradyomite and “csiklovaite”, but these phases need further investigations. It is to be noted that a few sulphide inclusions of the coarse crystalline calcite from the deep levels of the deposit proved to be stibnite.

Copper chlorides from the deep levels of the Recsk ore deposit

The recent mineral paragenesis that precipitated from the thermal waters (35–44 °C) in the adits driven on the –690 m and –890 m levels of the Recsk ore deposit was investigated in detail by Kiss & JÁNOSI (1994); they gave special attention to the magnesium-bearing phases. Hydrocarbonate, sulphate and chloride anions were found in the thermal waters using wet chemical methods. The cations of the minerals that crystallised from the ion-rich fluids could be derived either from the surrounding sedimentary (Ca, Mg) and magmatic rocks (Na, K) or from the ores (Cu, Zn). The high amount of chloride may come from sedimentary formations. The dominant chloride of the hydrothermal association is halite, but hydrohalite is also mentioned (albeit without any further data). Atacamite and eriochalcite — with “question mark” — are also mentioned as being present in the rare greenish, bluish chloride patches of the –890 m adit, but there is no documentation of this. The present research was able to identify both atacamite and eriochalcite with XRD and EDX measurements.

Atacamite — $\text{Cu}_2\text{Cl}(\text{OH})_3$ (which is orthorhombic), is the most common Cu chloride in the studied greenish, bluish crusts from Recsk. It was formed in the oxidation zones of copper deposits, especially during periods of arid climatic conditions. It is frequently observed in fumaroles (ANTHONY et al. 2003). At Recsk, atacamite forms dark green xenomorphic grains, irregular aggregates, 1–2 cm² size encrustations, or pulverulent coatings. It is to be noted that malachite, brochantite and some other green minerals were also mentioned by Kiss & JÁNOSI (1994) from the mineralisation of the deep levels of the Recsk deposit, but without any further data. Atacamite from Recsk was identified by XRPD (Table III). The calculated cell parameters (for $Pnam$ space group) are $a = 6.056\text{\AA}$, $b = 9.073\text{\AA}$, $c = 6.877\text{\AA}$, $V = 377.9\text{\AA}^3$. Cu and Cl were identified by EDX. Halite, blödite and tamarugite were identified in close association with atacamite. The most spectacular varieties are the intense green, dust-like coatings or encrustments of atacamite on 5–10 cm-long white, stalactitic aggregates of halite and blödite.

Eriochalcite — $\text{CuCl}_2 \times 2\text{H}_2\text{O}$ (which is orthorhombic), is a sublimation product of fumaroles, or an oxidation product of copper deposits produced during periods of arid climatic conditions (ANTHONY et al. 2003). However, in Recsk it was precipitated from hydrothermal fluids rich in copper and chloride ions. Eriochalcite forms bluish or yellowish green aggregates 2–4 mm in size; these are associated with halite, tamarugite and hexahydrite. Atacamite was not identified in its close association. Thick tabular intergrown eriochalcite crystals sometimes form dense

Wulfenite from the Szűzvár deposit, Pátka

The Pb-Zn-Cu-containing sulphide paragenesis and the secondary mineral associations formed from them were first described by KISS (1954). These were found in the adits opened for fluorite exploitation in the early 1950s, near the former Szűzvár Mill, Pátka. Near the sulphides, the strongly-altered parts of the silica-rich veins contain cavities usually filled with secondary minerals; these cavities are a product of weathering processes close to the surface. A strongly-weathered quartz vein of this type can be found on the surface even now, close to the original entrance of the mine. The investigated wulfenite specimens were collected here. The secondary minerals, especially plumbogummite, were examined by ZAJZON et al. (2004). They mentioned wulfenite in this paragenesis for the first time. Wulfenite — tetragonal, PbMoO_4 — usually occurs here together with pyromorphite, as pale yellow or off-white, tabular crystals, 2–4 mm in size. However, sometimes crystals up to even 2–4 cm in diameter can be found. The dominant form is the {001} basal pinacoid; {011}, {112}, {114} and {013} forms are represented by smaller faces only. A common crystal habit is where the small bipyramids alternate, producing a peculiar zigzagged shape (Figure 3). A “pure” bipyramidal habit is much rarer, the largest crystals of this type being 1–2 mm in size.

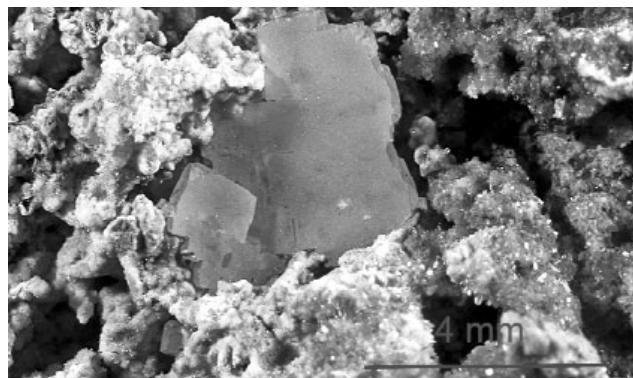

Figure 3. Tabular crystals of wulfenite with pyromorphite from the Szűzvár deposit, Pátka, Hungary

The largest crystal is 0.5 cm. Collection: S. KLAJ, photo: L. TÓTH.

A legnagyobb kristály 0,5 cm-es. KLAJ S. gyűjteménye. Fotó: TÓTH L.

XRPD data show a good match with ICDD card 00-044-1486, with regard to both d -values and intensities (Table V). Cell parameters of wulfenite from Pátka (calculated for a $I\bar{4}_1/a$ space group) are $a = 5.433\text{ \AA}$, $c = 12.110\text{ \AA}$, $V = 357.4\text{ \AA}^3$. Wet chemical analyses revealed minor $\text{Ca} > \text{Pb}$ and $\text{S} > \text{Mo}$ substitutions (Table VI). The chemical formulae calculated from the two analyses are:

- 1) $(\text{Pb}_{0.83}\text{Ca}_{0.03})_{\Sigma 0.86}(\text{Mo}_{1.04}\text{S}_{0.01})_{\Sigma 1.05}\text{O}_4$ and
- 2) $(\text{Pb}_{0.81}\text{Ca}_{0.04})_{\Sigma 0.85}(\text{Mo}_{1.03}\text{S}_{0.01})_{\Sigma 1.04}\text{O}_4$.

Pyromorphite and cerussite are the most common associated minerals and these were formed earlier than wulfenite. Sometimes oxyplumbboroméite (formerly bindheimite), malachite, azurite, more rarely plumbogummite and mimetite can follow them. The cations of the secondary

minerals are the same as those of the primary sulphides of the mineralisation; however, Mo could have originated from the molybdenite of a granite pegmatite of the closer environment (JANTSKY 1957). Nevertheless, optical spectroscopy results published by KISS (1954) did not indicate the presence of Mo in any of the samples collected from the oxidation zone of the ore-bearing veins at the Szűzvár mine.

Phillipsite-Na from the Bátonyterenyé coal mine

The investigated coal specimens are preserved in the mineral collection of the Herman Ottó Museum, Miskolc, Hungary. According to their registration label they came from an unspecified coal mine of the Nógrád coalfield, probably collected by István VITÁLIS. Phillipsite-filled veins penetrate these samples. The coal specimens show a hexagonal columnar structure, similar to that observed in the coked coal seams in the Pécs-Vasas open pit. In the latter, magmatic veins penetrated the coal beds and “baked” them on making contact. According to the XRPD data, the cracks are filled with a colourless, transparent mineral: phillipsite (Figure 4). The dominant extra-framework cation is Na, as proven by EMPA; thus the mineral is phillipsite-Na (Table VII). The crystals are always fourlings with pseudo-tetragonal symmetry (Figure 5). Phillipsite-Na is a product of the hydrothermal activity of the basalt dykes penetrating

Secondary bismuth minerals from the Ocna de Fier (Vaskő) ore deposit

KOCH (1948) was the first to mention “bismutosphaerite (= bismutite?)” from Ocna de Fier and bismutite from the Dognecea and Oravița ore deposits. “Bismutosphaerite”

appeared as yellowish brown patches or globular aggregates (up to 1 mm) on bismuthinite, while bismutite formed pseudomorphs after bismuthinite, and greenish or yellowish brown soft masses. An unspecified “bismuth ochre” was reported from the Dognecea–Ocna de Fier ore deposit from the paragenesis of “dognácskaite” by KRENNER (1884) and PAPP et al. (2012).

Bismutoferrite and bismutite were identified by XRPD and microprobe on a historical specimen from Ocna de Fier (without further data about the locality); this specimen is in the mineral collection of the University of Miskolc. Bismutoferrite is yellow and powder-like, while bismutite is white and forms hair-like aggregates. Both minerals are common in the specimens; they build “nests” up to 1–2 cm in the iron oxide – clay mineral matrix. XRPD data show good a match with bismutoferrite and bismutite ICDD cards (Table VIII). The different textural features can be observed well on the BSE image (Figure 6). Bismutoferrite appears as porous masses, whereas bismutite is a pseudomorph related to bismuthinite. The measured EDX composition of bismutoferrite is close to the theoretical values, but bismutite contains 8–10% Pb and 1–2% Ca as substituting elements. Both minerals have formed on the surface of the primary Bi sulphides as a product of weathering processes close to the surface.

Brianyoungite from the Săcărâmb (Nagyág) ore deposit

This rare $Zn_3(CO_3, SO_4)(OH)_4$ mineral was first described by LIVINGSTONE & CHAMPNESS (1993) as a recently-formed phase, found in an abandoned lead-zinc mine at Nenthead, Cumbria, England, UK. The mineral was accompanied by gypsum, smithsonite, goethite and pyrite.

At Săcărâmb, brianyoungite forms hair-like or radial aggregates of needles and laths up to 0.5 mm on quartz (Figure 7); these are in the cavities of tetrahedrite-pyrite rich quartz vein fillings. The investigated specimens were collected at the old waste site. Tetrahedrite, pyrite, sphalerite, and gypsum were identified from its close environment. XRPD data show a good match with those on the ICDD card (Table IX). According to the EDX data, brianyoungite from Săcărâmb contains a few wt% of Sb in addition to the major detectable constituents (Zn and S).

Spertiniite from the Băița [Bihor] (Rézbánya) ore deposit

Spertiniite — Cu(OH)₂ (which is orthorhombic), is a very rare mineral. At its type locality (Jeffrey mine, Québec, Canada) it was formed from chalcocite, in a rodingite dyke near the contact zone with a serpentized dunite; this took place in the presence of alkaline groundwater (GRICE & GASPARRINI 1981). It was identified as thin, blue crusts on the surface of native copper from the deep

levels of the molybdenum mine at Băița [Bihor]. XRPD data show a good match with those on the ICDD card 01-080-0656 (Table X). Only Cu and O were identified on the EDX spectra. It is most likely that it is an alteration product of native copper.

Konyaite efflorescences from Sărmașu (Nagysármás)

According to ANTHONY et al. (2003), konyaite — Na₂Mg(SO₄)₂ × 5H₂O (which is monoclinic), occurs in salt efflorescences on saline soils; it forms between 30 °C and 50 °C due to the evaporation of ground and surface waters. Its thin tabular crystals are 5–8 µm in diameter (Figure 8). White,

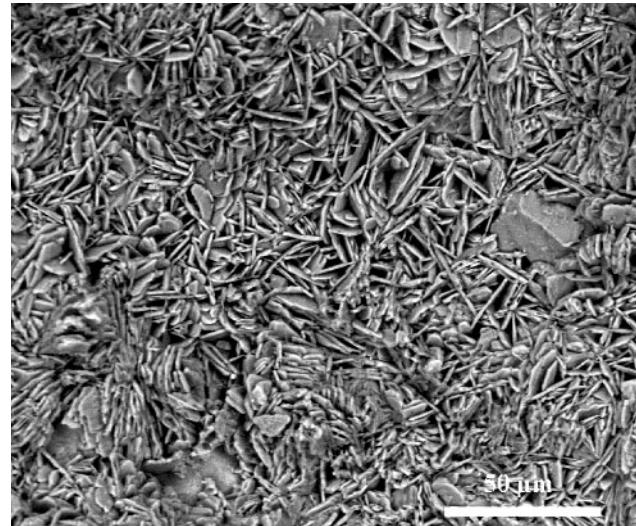

Figure 8. Tabular crystals of konyaite from Sărmașu, Romania. BSE image
8. ábra. Táblás konyaitkristályok. Nagysármás. BSE-kép

dust-like efflorescences collected on a hot, dry, summer day from the surface of the soil at Sărmașu proved to be konyaite with a minor amount of gypsum. It was identified by XRPD (Table XI). It is to be noted that salt efflorescences on soil surfaces are widespread in the Câmpia Transilvaniei (Mezőség) area, especially in the summer season. Their further mineralogical investigation is recommended.

Amarantite from the Smolník (Szomolnok) ore deposit

The pyrite deposit of Smolník — the type locality of three iron sulphates: rhomboclase, szomolnokite and kornelite — is

well known for its rich sulphate paragenesis (see ĎUĎA & OZDÍN 2012). A yellow, porous, sulphate-containing historical specimen from the collection of the University of Miskolc — labelled as copiapite — was reinvestigated. The reinvestigation was due to the presence of a few mm-size nests of orange-red, acicular crystal aggregates with vitreous lustre in the matrix. The yellow main mass proved to be butlerite — $\text{Fe}^{3+}(\text{SO}_4)(\text{OH}) \times 2\text{H}_2\text{O}$ (which is monoclinic), whereas the orange-red phase is amarantite — $\text{Fe}^{3+}\text{O}(\text{SO}_4)_2 \times 7\text{H}_2\text{O}$ (which is triclinic). It forms 1–1.5-mm long prismatic or lath-like crystals, which show perfect cleavage in one direction (Figure 9). Amarantite was identified by XRPD investigation (Table XII). The presence of iron and sulphur was proven by EDX.

Richelsdorffite from the Novoveská Huta (Iglóhuta) ore deposit

The Novoveská Huta ore deposit is famous for its secondary arsenates (see ŠUĐA & OZDÍN 2012) — $\text{Ca}_2\text{Cu}_5\text{Sb}(\text{AsO}_4)_4(\text{OH})_6\text{Cl} \times 6\text{H}_2\text{O}$ (which is monoclinic), which is also secondary in origin. It forms fan-shaped aggregates of 0.5–1 mm tabular crystals. According to the BSE images (Figure 10), these are chemically homo-

geneous, and their chemical composition is close to the theoretical values (Table XIII). The formula was calculated from the average of three analyses: $\text{Ca}_{1.94}\text{Cu}_{5.01}\text{Sb}_{1.04}(\text{AsO}_4)_{4.02}(\text{OH})_6[\text{Cl}_{0.79}(\text{OH})_{0.26}]_{\Sigma 1.05} \times x\text{H}_2\text{O}$. $x = 4.71$, if H_2O is calculated by difference. This is lower than the theoretical value (6) and is probably due to H_2O loss during analysis. The mineral is also identified by XRPD

(Table XIV). It is to be noted that these aggregates are overgrown on baryte crystals.

Some accessory sulphates from the Gemerská Hôrka (Gömörhorka) gypsum-anhydrite mine

Anhydrite and gypsum are the dominant sulphates of the Gemerská Hôrka evaporite deposit (LÓRINCZ 2008). Many accessory sulphates (hexahydrite, glauberite, blödite, epsomite, konyaite, thénardite and eugsterite) can be found in the thin or thick fibrous structures that fill the cracks of gypsum as products of secondary processes. XRPD (Figures 11–12) and EDX (major chemical components) were used to identify these species. Based on XRPD studies, here they form four typical associations:

- 1) epsomite–thénardite–gypsum,
- 2) glauberite–thénardite–gypsum,
- 3) konyaite–hexahydrite–blödite,
- 4) thénardite–eugsterite–gypsum.

Blödite forms white, flour-like masses and it is probably an alteration product of the very unstable konyaite and hexahydrite (see MILLS et al. 2010). Hexahydrite can also

13. ábra. Idiomorf cölesztin- (fehér) és anhidritkristályok (halványszürke) gipszben (szürke). Gömörhorka (Gemerská Hôrka, Szlovákia), Fortuna-tároló. BSE-kép

occurs alone as fibrous aggregates of white needles or laths.

Epsomite and glauberite were described in the cracks of gypsum from the gypsum-anhydrite mine of Perkupa, Hungary by MAURITZ & CSAJÁGHY (1953), while MIKLÓS (1987) mentioned hexahydrite, thénardite, glauberite and

epsomite from the gypsum-anhydrite mine of Alsótelekes, Hungary. Both localities are similar in age and genetics to that at Gemerská Hôrka.

It is important to add that celestine crystals of 20–40 µm size were identified in the massive gypsum deposit, together with idiomorphic anhydrite (Figure 13); these most probably represent a product of relict phases. Similar celestine occurrences were also reported by MIKLÓS (1987) from Alsótelekes.

Acknowledgements

The authors are grateful to Árpád LÓRINCZ (Gemerská Hôrka) for the samples from the Gemerská Hôrka gypsum-anhydrite mine, Dr. Rudolf ĎUĎA (Košice) for the richelsdorffite, Lajos KÖVECSÉS-VARGA (Siófok) for the spertiniite, Gábor KOLLER (Szentendre) for the brianyoungite, the late Tibor NAGY (Pilisborosjenő) for the first wulfenite, and Szabolcs TÓTH (Recsk) and the late Dr. Béla KUN (Gyöngyös) for the galenobismutite–bismuthinite samples.

This work was supported by the grant TÁMOP-4.2.1.B-10/2/KONV-2010-0001.
