Abstract

Terroir refers to the geographical origin of wines. The landscape factors (topography, parent rock, soil, microbial life, climate, natural vegetation) are coupled with cultural factors (cultivation history and technology, cultivars and rootstock) and all together define a terroir. The physical factors can be well visualized by a slope profile developed into a pedosequence showing the regular configuration of the relevant physical factors for a wine district. In the present study the generalized topographic pedosequence (or catena) and GIS spatial model of the Villány Hills, a historical wine producing region, serves for the spatial representation and characterization of terroir types. A survey of properties of Cabernet Franc grape juice allowed the comparison of 10 vineyards in the Villány Wine District, Southwest Hungary. Five grape juice properties (FAN, NH₃, YAN, density and glucose + fructose content) have been found to have a moderate linear relationship ($0.5 < r^2 < 0.7$) with the Huglin Index (HI) and aspect. Aspect, when determined on the basis of angular distance from South (180°), showed a strong correlation ($r^2 > 0.7$) with FAN, NH₃, YAN, sugar and density and moderate correlation with primary amino nitrogen (PAN). HI showed a correlation with three nitrogen related parameters FAN, NH₃, YAN, density and glucose + fructose content. Elevation and slope, however, did not correlate with any of the chemical properties.

Keywords: pedosequence, GIS, terroir, soils, grape juice properties, Huglin Index

Introduction

The concept of terroir is widely used to explain the unique quality of agricultural products, first of all, of wines. Terroir refers to the geographical origin of wine, the particular interaction of ecosystem factors, including local rocks, topography, climate, soil and others (BIANCOTTI, A. 2003; VAUDOUR, E. *et al.* 2005; GLADSTONES, J. 2011; FRAGA, H. *et al.* 2014). The biophysical factors are combined with cultural elements (cultivation history, cultivars and rootstocks, viticultural and oenological techniques etc.) to produce

a wine of individual character (SEGUIN, G. 1986; UNWIN T. 2012). The usefulness of the terroir concept has been recently supported by GIS tools (BALLA, D.Z. *et al.* 2019) whereas its applicability is also confirmed by its rapid spreading from Europe (e.g. FALCETTI, M. 1994; WILSON, J. 1998) to all other continents where grapes are grown (JACKSON, D. and LOMBARD, P. 1993; e.g. in Canada: HAYNES, S.J. 2000; in South Africa: WOOLDRIDGE, J. 2000; in Australia: HALLIDAY, J. 2007). The terroir may be an elusive term sometimes but it provides a very stable background to grapes and wine production. JACKSON, D.

and LOMBARD, P. (1993) underline that it is mainly the concept of terroir that explains how the appellations of the French wine districts could maintain their quality over centuries. In those districts a huge collective knowledge has accumulated on the interactions between the biophysical environment and the practices applied in vitiviculture (VVC) which is recognizable in the quality of wine (OIV 2008). The terroir concept also extends to the landscape transformation caused by grapevine cultivation, its literary and fine arts reflections and is used in wine marketing strategies (VAUDOUR, E. 2001; JORDÁN, GY. et al. 2005; SZILASSI, P. et al. 2006).

Although it is impossible to define the ideal climate (temperature, rainfall amount and regime or solar radiation) and the best possible soil for vine growing and wine production, all these complex factors have to be considered in their interactions when terroir is described and assessed (VAN LEEUWEN, C. and SEGUIN, G. 2006; VAN LEEUWEN 2010; FERRETTI, C.G. 2019). The complex interactions explain why the terroir is a typically holistic concept (MALHEIRO, A.C. et al. 2010; FRAGA, H. et al. 2018).

Topography (slope conditions) is a fundamental component of the terroir as it influences the distribution of parent rock outcrops, some physical and chemical properties of soils and slope deposits, microclimate and natural vegetation (FRAGA, H. et al. 2014). Elevation, slope angle and aspect are equally influential (JONES, G.V. 2004). Even a 100 m difference in elevation between the top and bottom of the slope may reflect variation within the terroir of the same vineyard plot. Slope inclination and aspect impact on radiation balance, soil erosion, drainage and management (ZSÓFI, Zs. et al. 2011). Where steep slopes require terracing (ŠMID HRIBAR, M. et al. 2017), the artificial slope form leads to a fundamental transformation of the terroir.

Among soil parent materials, limestone (the rock building the Villány Hills) has a good nutrient supply to grapes, good drainage but retains moisture under dry weather conditions. There is a single negative effect of carbonates: they cause iron deficiency in

grapes (TAGLIAVINI, M. and ROMBOLÀ, A.D. 2001). Calcareous soils support excellent blends like Aube in Champagne, Chablis in Burgundy, Pouilly and Sancerre in the Loire Valley and Côtes du Rhône in the Lower Rhône Valley (WILSON, J. 1998).

Physical and chemical soil properties influence grapevine growth and eventually wine quality (MACKENZIE, D.E. and CHRISTY, A.G. 2005; QI, Y.B. et al. 2019). Good wines are produced on a wide range of soils (WANG, R. et al. 2015; WARMLING, M.T. et al. 2018) and soil texture may vary from skeletal soils to those with 60 per cent clay (SEGUIN, G. 1986). Grape juice properties are clearly correlated with plant-available trace elements (Ca, Sr, Ba, Pb and Si) in the soil (MACKENZIE, D.E. and CHRISTY, A.G. 2005). If water supply and nitrogen availability are limited, vine vigour, berry weight and yield decline, while sugar content, anthocyanin and tannin concentrations increase in berries (MATTHEWS, M. and ANDERSON, M. 1988, 1989; CHONÉ, X. et al. 2001; HILBERT, G. et al. 2003). These 'deficiencies' in soil properties are beneficial to grape quality potential for red wine making. On the other hand, insufficient soil depth and soil compaction hinder moisture storage, root growth and aeration (JACKSON, D.I. and LOMBARD, P.B. 1993). In the Villány Hills the loess mantle compensates for shallow soil depth, but low soil water storage capacity is a risk factor in a region under Mediterranean influence, manifested in increasing heat and water stress (TARDAGUILA, J. et al. 2011). The microbiome in vineyards interacts with the host vine stock, there is a symbiotic relationship between soil and the microbes, which release nutrients from the soil, fix nitrogen, mitigate environmental stresses (drought or toxic contaminants) (GILBERT, J.A. et al. 2014). Each wine district (or even terroir) has its own microbial communities which indirectly influence grapes and wine quality (BARATA, A. et al. 2012).

Topographic and soil variations among terroir units can be best demonstrated on topographic pedosequences. Supplemented with the visualization of GIS data the catena is suitable to indicate microclimate, therefore pre-

senting soils as one of the major components of the terroir (FRAGA, H. *et al.* 2014). When soils are considered as integral parts of terroir, then specific terroir units can be more closely related to viticultural data, as well as must properties (VAUDOUR, E. 2002, 2003; DELOIRE, A. *et al.* 2005; BRAMLEY, R. and HAMILTON, R. 2007).

Climatic factors limit the geographical distribution of grapevine growing and wine vigour and the distribution of white and red wines are also related to topographic, soil and climatic conditions (FRAGA, H. *et al.* 2013). The Winkler Index defines the climatic conditions suitable for grapevine cultivation classifying the climate of wine-producing regions based on heat summation or growing degree-days (WINKLER, A.J. 1974). Its modified version, the Huglin Index (HUGLIN, P. 1986), is based on the temperature sum over the temperature threshold of 10 °C for all days from beginning of April to end of September. The Plant Cell Density Index (PCD) is the ratio of reflected infrared (NIR) to red light (R) ($PCD = NIR/R$) gives a surrogate measure of vine vigour (HALL, A. *et al.* 2002).

Plant protection measures are also site property dependent. Topography influences the occurrence of and damage by some fungi. Interpreting abiotic site factors, new advisory platforms give guidance and end-user information for phytosanitary decision-making including predictions of infection risks for key pathogens identified by satellites and terrestrial radar systems and precisely located by GPS (see e.g. GABEL, B. 2019).

In landscape ecology, the consequences of land use changes are also studied along catenas and for individual terroirs (JORDÁN, GY. *et al.* 2005; LÓCZY, D. and NYÍZSALOVSKAI, R. 2005; SZILASSI, P. *et al.* 2006; NOVÁK, T.J. *et al.* 2014).

The paper attempts to prove that the toposequence concept is a correct methodological approach to spatial modelling of the terroir. A soil catena was first explicitly described by MILNE, G. (1935) and his colleagues in East Africa in the 1930s (BORDEN, R.W. *et al.* 2020). The catena became widely adopted in and beyond soil science. Now it is used by ecologists, geomorphologists and hydrologists amongst

others. In a modern interpretation the catena indicates spatial patterns of soil and vegetation consistently located in specific topographic positions and is used synonymous with 'toposequence' (BASKAN, O. *et al.* 2016). The simplicity, appeal and longevity of the catena concept (RADWANSKI, S.A. and OLLIER, C.D. 1959; OLLIER, C.D. *et al.* 1969) makes it suitable for the integration of interdisciplinary research in geomorphology, soil science, hydrology, environmental history and other disciplines related to landscape studies.

Recently, several terroirs have been identified in the Villány Wine District: Jammertal, Csillag-völgy (*Sterntal*), Remete (*Einsiedler*), Ördög-árok (*Teufelsgraben*), Kopár. The differences between their natural potentials for grapes cultivation largely depend on their position on the toposequence.

The objectives of the present study were to interpret a typical pedosequence revealing a regular geographical pattern of environmental factors (slope parameters, parent material, soils, microclimate, natural vegetation etc.) for the characterization of the terroir. The Villány Hills, selected for investigation, is a well-defined wine district with a relatively simple geology and geomorphology. Therefore, a single typical topo-pedosequence is able to represent the configuration of geographical terroir factors (SWITONIAK, M. *et al.* 2017; CZIGÁNY, SZ. *et al.* 2018).

Although a single parameter of grape juice or wine cannot comprehensively characterize a terroir, we attempt to reveal variations in nutrition properties of grapes from different vineyards of the Villány Wine District. In 2018 and 2019 the local producers of Cabernet Franc, a variety getting increasingly popular in the region, agreed to harvest grapes at the same date and to use the same technology in wine making. The objective of the present paper is to compare the impact of the physical environment on wines from 10 plots in different locations and to draw correlations between the topographic parameters of vineyards and the nutritional properties of their produces. The paper is *not* aimed at establishing a ranking among the studied terroirs.

Study areas

Location

The Villány Wine District extends over various altitudinal regions of the Villány Hills, SW-Hungary (Figure 1), stretching ca. 30 km in an east-western direction from the village of Hegyszentszárd to the small town of Villány (Figure 2).

Lithology and topography

The Villány Hills form the southernmost hill range in Hungary. The hills are predominantly built up of Triassic, Jurassic and Cretaceous limestones and dolomites, covered by Pleistocene loess at lower elevations (Lovász, Gy. and Wein, Gy. 1974; Lovász, Gy. 1977). In summits

of the eastern and western ends limestone and dolomite commonly outcrop (Wein, Gy. 1967). The range constitutes of uplifted and imbricated horsts. The sedimentary rocks that form the bulk of the range were thrust on each other in a thrust fault style forming blocks or ‘shingles’ (Dezső, J. et al. 2004; Sebe, K. 2017). The blocks are bordered by fault lines that dip to the West (Lovász, Gy. 1977). The blocks are tilted to the West or Northwest, in the case of the Csarnóta block to the South and in the Szársomlyó block to the North. Additional Mesozoic horsts and outcrops are found in the southern foreground of the range including the Siklós Castle Hill, the Beremend Hill and the Kistapolca Hill (Czigány, Sz. 1997). The summit regions are covered by shallow loess-like sediments and soils in a discontinuous fashion, while limestone caverns are filled in by Pliocene red clay (Lovász, Gy. 1973).

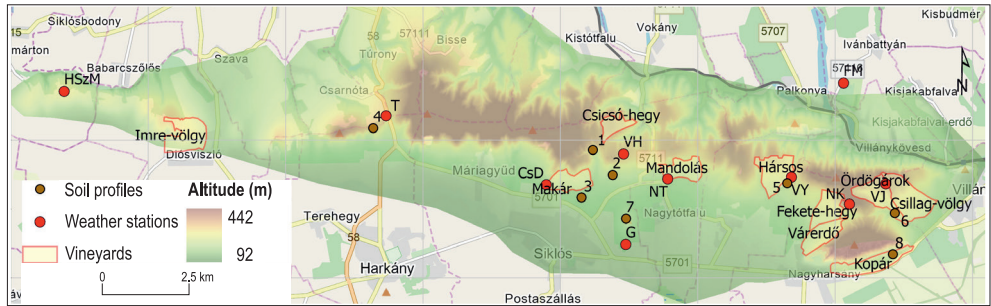

Fig. 2. Map of the Villány Wine District with locations of the studied vineyards, soil profiles and meteorological stations. Soil profiles: 1 = Melegmál; 2 = Városhihegy-dűlő; 3 = Zuhánya-dűlő; 4 = Kopasz Hill, Csarnóta; 5 = Feketehegy, Vylyan vineyard; 6 = Ördögárok; 7 = Göntér; 8 = Kopár. Meteorological stations: HSZM = Hegyszentmárton; T = Túrony; CsD = Csukma-dűlő; VH = Városhi-hegy; NT = Nagytótfalu; G = Göntér; VY = Vylyan winery; FM = Fáni-major (not used for meteorological analysis); NK = Nagyharsány-Konkoly; VJ = Villány-Jammertal (Background: OpenStreet Map/ArcGIS, 5-meter DEM)

The highest point of the westernmost block is 268 m (Kopasz Hill). Here the limestone is extensively found on the surface and exposed in the Csarnóta Limestone Quarry. The average height of the block to the East (Csukma block) is around 340 m with Tenkes Hill (408 m), which is the second highest peak in the entire range. The summit elevation then decreases to about 240 m in the central, lowest part of the range (Város Hill block) North of the town of Siklós. Here, in this block, the consolidated bedrocks (limestones and dolomites) are only exposed in road cuts, gullies and ravines. To the East the range again gains height (Fekete Hill, 358 m). The highest point of the hills is Szársomlyó (442 m). The Ördögszántás ('Devil's ploughfield') is a lapiés field carved on the faces of the north-dipping limestone strata on the southern slopes of Szársomlyó Hill. Here loess only covers the northern and the southern foothills (LOVÁSZ, Gy. and WEIN, Gy. 1974; CZIGÁNY, Sz. 1998).

northern slopes. The loess-covered northern slopes and summit regions are dominated by silver lime (*Tilia tomentosa*), hornbeam (*Carpinus betulus*), pedunculate oak (*Quercus robur*), Turkey oak (*Quercus cerris*) and locally by beech (*Fagus sylvatica*). The natural vegetation on the southern slopes is a xerothermic wooded grassland on karst spotted with sparse rocky grasslands (BORHIDI, A. and DÉNES, A. 1997). A typical Mediterranean karstic steppe is found on the limestone surface of the southern slopes of the Szársomlyó Hill, with downy oak (*Quercus pubescens*), South European flowering/manna ash (*Fraxinus ornus*) and invasive tree of heaven (*Ailanthus altissima*). The loess-covered southern hillslopes are used as vineyards (TENGLER, T. 1997). The dirt roads leading to the vineyards have developed into sunken lanes which built alluvial fans of loess deposits at the base of slope (CZIGÁNY, Sz. 1997; CZIGÁNY, Sz. and NAGYVÁRADI, L. 2000).

Climate

Vegetation and land use

There is a pronounced mesoclimatic and vegetational contrast between the southern and

The region is located in the semi-humid temperate zone with hot summers (LOVÁSZ, Gy. 1977; KOTTEK, M. et al. 2006), ustic soil moisture and mesic temperature regimes according to

the USDA's Soil Taxonomy. Mediterranean and arid continental influences are also present. Mean annual temperature is 10.8 °C (for 1971–2000, recently 12.0 to 13.2 °C) and average temperature of the coldest month (January) is -0.5 °C, while the warmest month is July with mean temperature of 22.5 °C. The average annual precipitation total is around 680 mm in the region. The 30-year average value is 661 mm for the town of Siklós, 684 mm for Nagytótfalu, 694 mm for Villány, and 701 mm for the town of Harkány (1971–2000 data, Hungarian Meteorological Service, OMSz). Based on the 1981 to 2010 meteorological record, February is the driest (32 mm), while the highest precipitation (83 mm) is recorded in June (Bötkös, T. 2006).

Methods

Soil sampling

Four representative soil profiles were excavated along the southern slopes of the Villány Hills from the ridge to the southern foothill position and further four profiles were used for verification. Profiles were manually excavated to a depth of about 120 cm or to the depth of the parent material. Profile locations were selected according to slope position, parent material and land use. Soil profiles were described and classified: master and diagnostic horizons were determined according to the WRB (World Reference Base for Soil Resources; Guidelines for soil description by FAO 2006; IUSS Working Group 2015;). Munsell color, field moisture conditions and soil structure of each horizon were determined in the field.

Disturbed soil samples were then taken from the centre of each horizon and were analysed in the laboratories of University of Pécs and University of Debrecen for particle size distribution. Particle size distribution was determined using a MasterSizer 3000 (Malvern Inc. Malvern, United Kingdom) particle size analyser, and combined wet sieving (2.0–0.2 mm fractions) and the pipette method (<0.2 mm fractions) (PANSU, M. and GATHEYROU, J. 2006).

Spatial visualization of climate data

Climate data were obtained from 9 meteorological stations, maintained by the Tenkes Wine Region Management Corporation (see Figure 2). Sensors of the stations were manufactured by the Boreas Ltd. (Érd, Hungary). Weather data included air temperature, precipitation, insolation, relative humidity, wind speed and wind direction. Only the year 2013 was devoid of hiatus, hence it was selected for the calculation of the Huglin Index (HI), used for the evaluation of climatic influences on terroir properties. Eventually, HI is a method for classifying the climate of wine growing regions based on heat summation of growing degree-days (HUGLIN, P. 1986). The index assumes that growth of the grape plant begins when daily mean temperature reaches 10 °C in the spring and was calculated for the days when the 5-day moving average of daily mean temperatures reached a minimum of 10 °C (growing season) with the following equation:

$$HI = \frac{T_{min} + T_{max} - 20}{2}, \quad (1)$$

where T_{min} and T_{max} are the daily minimum and maximum temperatures during the growing season, respectively.

All point weather data were then interpolated and weighted according to the 2013 raster based insolation GIS database of the area. Correlation between the incoming solar radiation of the nine weather stations and HI was calculated by fitting a linear trend line on the corresponding data in a form of $y = ax + b$. (The actual equation is $y = 0.0033x - 1,813.2$.) Derived temperature data were further weighted as a function of vertical elevation gradient at a rate of 0.65 °C decrease of temperature for each 100 m elevation increment. All raster calculations were done in ArcGIS Pro software environment.

Vitivinicultural data and statistical analyses

Ten vineyards were selected for verification purposes of the terroir-catena approach model (see Figure 2). Tartaric acid, malic acid, pH,

primary amino nitrogen (PAN), free amino nitrogen (FAN), NH_3 content, yeast assimilable nitrogen (YAN), density, °Brix and sugar content (glucose + fructose) of Cabernet Franc grape juice, obtained from vintners, were used for model verification. Correlation coefficients (r^2) using linear relationships were then determined between the vitivincultural (VVC) properties and the factors influencing terroir properties (HI, elevation, slope inclination and aspect). Anova statistics and cluster analysis were run using PAST 2.0 software for the must properties of each vineyard.

Results and discussion

Soil genesis and systematic position

The investigated soil profiles exhibit a high diversity of soils. The pedosequence represents

a typical series of soils starting from the summit, covered by loess, overlying the weathering products of limestone. From the steepest slope sections the loess cover has been eroded or has not even accumulated. Therefore, the (weathering residue of) limestone outcrops. These are mostly protected areas, preserving the native vegetation cover, with farming activities precluded (Figure 3, Table 1).

Profile 1 (45°52'45.19"N, 18°18'57.67"E) was excavated in the Meleg-mál vineyard, located in a relatively gently sloping summit position covered by loess deposits (soil parent material). The upper section and the most convex segment of the slope is covered by *Endocalcaric Cambisol* (Siltic, Ochric) (IUSS Working Group 2015) (Figure 3, a; Table 1, Profile 1). The texture in the entire soil profile is typical of soils formed on loess deposits, i.e. mainly silty loam.

Profile 2 (45°53'06.2"N, 18°13'53.7"E) was excavated South of the village of Csarnóta, East

Fig. 3. of Kopasz Hill, on a karstic surface with limestone blocks on surface, at the edge of a quarry, with the surface above having an inclination of 3° at an elevation of 191 m (Figure 3, b; Table 1, Profile 2). Due to the shallow topsoil, the soil is classified as *Somerirendzic Leptosol* (Humic, Siltic). Particle size distribution is dominated by silt and partly by clays, classified as silt loam. Highest clay contents are observed in the B_w and BC horizons. Profile 2 represents a soil developed on limestone outcrops (qualifier *Rendzic*) and its clayey weathering products, containing sand and silt fraction with silty loam texture throughout. The most important feature of the profiles is the presence of coarse fragments in the subsoil and the shallow, carbonate-rich, humic surface epipedon. Soil depth in the vicinity of the profile is highly variable, but generally less than 55 cm.

Profile 3 (45°52'23.6"N; 18°19'11.2"E) was excavated in the Városi-hegy in a midslope position with SSE aspect and an inclination of 5° at an elevation of 154 m (Figure 3, c; Table 1, Profile 3). In terms of land use this had been a vineyard until 2001, when it was left fallow. The soil is classified as Haplic Luvisol (Aric, Cutanic, Humic, Pantosiltic, Protocalcic) with silt loam texture. Clay accumulation characterizes the profile below the depth of 40 cm. It is a *Haplic Luvisol* (Aric, Cutanic, Humic, Pantosiltic, Bathycalcic) developed predominantly on colluvic material and reworked loess-paleosol deposits. The profile was excavated in an abandoned vineyard where cultivation ceased in 2002. The profile indicates a certain degree of leaching and clay translocation, texture is dominated by the silt fraction (Pantosiltic). Since this part of the Villány Hills has been cultivated for the longest time, redeposited sediments accumulated by both natural slope processes and viticulture practiced since Roman times (Aric).

Profile 4 (45°52'05.6"N; 18°18'34.4"E) was excavated in an actively cultivated vineyard on a very gentle slope inclination of 3° at an elevation of 124 m in foothill position (Figure 3, d; Table 1, Profile 4). Classified as a *Calcaric Luvisol* (Aric, Cutanic, Humic, Pantosiltic) similar to Profile 3, it represents a relatively young

soil developed as a consequence of *colluvic* accumulation (supplementary qualifier *Colluvic*), transported from upslope by erosion since the area was arable land in the past (Aric) (Lovász, Gy. 1977; TENGLE, T. 1997; CZIGÁNY, Sz. 1998). The texture of slope deposits is mainly silt (*Pantosiltic*). The *colluvic material* has a humic character in the entire profile, probably due to the erosion of topsoil further upslope.

Two profiles out of the four soil profiles used for verification purposes are located in foothill position: Kopár and Ördög-árok. Yet they have a relatively shallow soil of about 50 cm, underlain by loess deposits (see Table 1). For the Kopár, the actual topsoil had a depth of only 5 to 15 cm. The soil profile in the Vylyan vineyard (Table 1, Profile 6) is in mid-slope position with a soil depth of 55 cm and with a buried topsoil between 55 and 75 cm. Oddly, the Göntér profile (Table 1, Profile 7), despite its plateau (summit) position exposed a heavily ploughed and relatively shallow soil with limestone boulders already occurring at a depth of 55 cm.

Characterization of the pedosequence

The typical pedosequence of the Villány Hills (Figure 4) was generated by the parent materials (limestone, loess and colluvium), topography and subsequently modified by agricultural activities and natural erosional processes. With the exception of Profile 1, the properties of all analysed profiles, were strongly influenced by human-induced erosion. (Profile 1 is a fairly natural profile on a very gentle slope of the plateau. Erosional processes did not remove the loess cover completely, only inhibited deeper soil development and organic carbon accumulation. Profile 2 is located in the erosional section of the investigated slope. The shallow soils here are discontinuous and scattered, altering with rock outcrops without any soil cover. Formerly, Profile 2 may have also been covered by loess, but we may also deduce that dust deposition itself was not possible here due to steep slopes, and soils have always developed on weathering products of limestone (Leptosols).

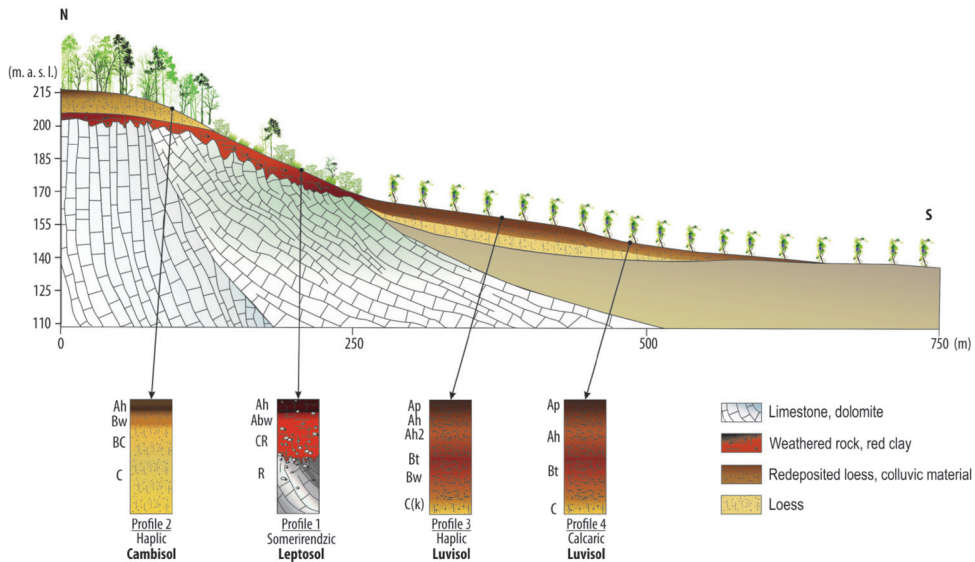

Fig. 4. Typical topographic pedosequence of the southern slopes of the Villány Hills (by CZIGÁNY, Sz. and NOVÁK, T.J.)

Nevertheless, the presence of former and existing Cambic B_w or even Argic B_t horizons is also possible in the case of thicker weathered material, which could be eroded later as a consequence of human influence (deforestation, grazing etc.). Today Profile 2 is heavily eroded: the shallow topsoil may have been truncated. Intense derasional processes must have occurred here in the past, probably due to land use (quarrying, vineyards), but also for natural reasons (steep slope, lack of dense forest cover). However, lately, over the past decades, no tillage has been practiced.

Soils developed on redeposited colluvial deposits dominate the middle and lower sections of slopes (profiles 3 and 4). Currently, slope processes have been restrained by grass vegetation and no-till viticulture, which also leads to organic matter enrichment. In Profile 4 humus accumulation was detected in the pedon – probably due to manuring and mineral fertilization.

The impact of erosion, horizontal translocation and re-deposition according to slope position is reflected in the systematic sequence of the described soils. Profile 1

has been markedly eroded and truncated. Therefore, profile development is poor and it was classified as a Cambisol. Profile 2 with shallow Humic and Calcic horizons, but a significant amount of coarse limestone fragments, was classified as Leptosol. Profiles 3 and 4 are both colluvial soils classified as Luvisols. Marked human impact is clearly visible in Profiles 2, 3 and 4, as their upper sections have been eroded, redeposited and transformed into material with coarse granular structure.

Spatial pattern of climate data

The weighted and interpolated map of the HI indicated the marked insolation and temperature variations as a function of slope aspect and elevation. Although elevation differences are limited and relief is subdued in the Villány Hills, topography still has a profound impact on temperature distribution.

Due to the globally observed increasing temperatures heat indices have regularly exceeded the preferred range of the commonly

grown grape varieties of the Villány region over the past years. That was especially true for the relatively warm year of 2013. HIs of 2013 commonly exceeded 21 °C-day on the southern slopes of the Villány Hills. These are markedly higher than the preference of the commonly grown grape varieties of the Villány region (Figure 5).

Mean HIs ranged between 1,749 and 2,060 degree-hours for the studied 10 vineyards (Table 2). The lowest value was found for the Várerdő vineyard located in the north-eastern foreground of the Szársomlyó Hill. The highest value was found in the Kopár vineyard in the south-eastern foothills of the Szársomlyó. Vineyards in plateau positions, despite their somewhat higher altitude, still had high HIs around 2,000 degree-hours. Csicsó-hegy was the only exception among the vineyards in plateau positions, with a mean HI of 1,896.

Spatial distribution of topographic parameters

Aspect played an important role on the selection of the studied vineyards. Aspect shows a great variability among the studied vineyards. The Várerdő vineyard had the theoretically less favoured WNW average aspect, with a range from SE to NNW (Table 3). The

Table 2. Spatial statistics of the Huglin Index for the ten studied vineyards

Vineyard	Mean	STD	Median
Hársos	1,983.83	84.87	1,987
Várerdő	1,749.81	60.97	1,716
Fekete-hegy	1,966.20	103.22	1,978
Kopár	2,060.50	51.34	2,093
Csillag-völgy	1,959.49	83.00	1,963
Ördög-árok	1,943.83	158.58	1,994
Imre-völgy	1,949.16	100.49	1,953
Mandolás	2,003.55	72.41	2,009
Makár	2,005.02	65.85	1,998
Csicsó-hegy	1,900.54	100.87	1,896

Mandolás, Makár, Hársos, Csicsó-hegy and Kopár vineyards face almost exactly to the South, however, the first four of them essentially found in plateau position with relatively gentle slopes.

In the Villány Hills the elevations of vineyards range from 100 to 279 m (Table 4). Higher elevations have a lower chance of frost damage in cold winters. In two consecutive winters of 1985–1987 frost severely affected large areas at the foothills. Similarly, lower elevations, due to higher relative humidity values, have a larger potential for fungal diseases. Elevation ranges are up to 132 m. Summit vineyards and Kopár have the lowest range. Kopár is located lowest (122 m) and Csicsó-hegy is the highest (234 m).

Fig. 5. Spatial distribution of the Huglin Index in the studied area

Table 3. Spatial statistics of aspect for the ten studied vineyards

Vineyard	Min, °	Max, °	Range, °	Mode, °	Mean, °	Abs 180-mean, °

Várerdő	212.47	341.57	129.09	284.18	297.24	117.24
Fekete-hegy	175.24	316.91	141.67	191.00	192.02	12.02
Kopár	147.99	209.05	61.06	176.67	180.61	0.61
Csillag-völgy	0.00	357.09	357.09	176.18	177.40	2.60
Ördög-árok	7.13	325.01	317.88	154.71	164.85	15.15
Imre-völgy	50.71	206.03	155.32	175.84	175.81	4.19
Mandolás	132.34	247.89	115.55	176.68	173.33	6.67
Makár	120.43	225.00	104.57	175.55	171.12	8.88
Csicsó-hegy	0.00	345.96	345.96	197.07	195.18	15.18

Table 4. Spatial statistics of elevation for the ten studied vineyards

Vineyard	Min, m	Max, m	Range, m	Mean, m	STD	Median, m
Hársos	147	235	88	195.76	24.29	200
Várerdő	130	223	93	168.21	22.81	167
Fekete-hegy	141	268	127	185.54	27.73	181
Kopár	100	162	62	121.59	14.61	121
Csillag-völgy	141	273	132	197.25	40.15	187
Ördög-árok	149	279	130	215.71	34.36	217
Imre-völgy	110	213	103	155.70	30.81	148
Mandolás	136	200	64	159.08	15.27	156
Makár	123	200	77	148.64	15.46	144
Csicsó-hegy	200	250	50	233.57	12.01	235

Generally, mean slope inclination remained below 10° for 9 of the studied vineyards, with the exception of Ördög-árok, where mean slope inclination reached 11.54° (Table 5). Vineyards in plateau positions generally had a mean slope inclination of less than 6°, hence they are preferred for viticulture.

Spatial correlations among terroir factors and must properties

The current study revealed the effect of HI, elevation, slope, aspect and soil on grape juice properties for 10 selected vineyards in the Villány Hills (Table 6). Elevation and slope did not show correlation with any of the VVC parameters. HI and aspect had a moderate linear relationship with 5 VVC parameters with r^2 ranging between 0.5045 and 0.6954. HI showed a correlation with four nitrogen related parameters (FAN, NH₃, YAN), density and glucose + fructose content, while aspect

showed moderate correlation with PAN. Aspect, when determined on the basis of angular distance from South (180°) showed a strong correlation ($r^2 > 0.7$) with FAN, NH₃, YAN, sugar content (fructose + glucose) and density.

Based on cluster analysis of all studied parameters (terroir and VVC parameters), three vineyard clusters were identified (Figure 6). The Várerdő vineyard with dominantly NW, NNW (297°) facing slopes forms an outlier. The second cluster included the Csillag-völgy, Imre-völgy, Ördög-árok and Csicsó-hegy. In this latter cluster vineyards are characterized by relatively high relief and large topographical differences, with medium HIs. The third cluster, encompassing the Fekete-hegy, Hársos, Makár, Mandolás and Kopár vineyards included areas with the relatively low relief and high indices. In this cluster Fekete-hegy is located on gentle slopes, Kopár in a foothill position while the remaining three are positioned on flat summits in the central section of the range.

Table 5. Spatial statistics of slope for the ten studied vineyards

Vineyard	Min, °	Max, °	Range, °	Mean, °	STD
Hársos	0.45	10.42	9.97	4.86	2.00

Conclusions

The complexity of a terroir calls for a holistic approach to grabbing its essence. Former literature has pointed out significant spatial differences in pedological and topographical properties within single vineyards, with a subsequent spatial variability on the growth and development of the vine shoots, berries as well as grape quality (e.g. CHENG, G. *et al.* 2014; BALLA, D.Z. *et al.* 2019). Although the topography and morphology of the Villány Hills are relatively simple, in accordance with the findings of former works (e.g. OUGH, C.S. and KRIEL, A. 1985; UBALDE, J.M. *et al.* 2010; PETROVIC, G. *et al.* 2019), our results revealed a relationship among topographical properties (elevation, aspect and slope), soil variability and selected chemical properties of the grape juice. Hence, alongside the spatial patterns of management techniques (COLLER, E. *et al.*

2019), the infinite combinations of biophysical factors generate a great diversity of terroirs in the area. Explaining the distribution of rocks, slopes, soils, water availability, microclimate and natural vegetation, in our opinion, the topographic pedosequence is an equally complex concept, which is capable of reflecting many of the essential properties of a terroir.

Nonetheless, functional relationship has only partially been found between the various abiotic and chemical properties. The probable reason for this is the complex influence of abiotic factors on must quality, and, in general, on the physiology of the grape. Therefore, the terroir cannot be broken down into a series of individual indicators. Favouring relatively gentle slopes and considerable soil depths, the majority of the studied vineyards are found in either foothill or plateau positions. This heterogeneous topographical distribution, is found to be at least partially reflected in VVC chemical properties, including FAN, NH_3 , YAN, sugar content and density. Soils of the Villány Hills, found on plateaus and foothill positions tend to have deeper root systems and grow on a soils of higher organic matter content, as organic matter either remain non-transported (plateaus) or is transported to the gentle slopes of foothill positions (KENDERESSY, P. and LIESKOSKÝ, J. 2014; KIRCHHOFF, M. et al. 2014). Equivocally with the results of TARDAGUILA, J. et al. (2011), soils in the southern slopes of the Villány Hills, mixed with colluvial sediments in foothill positions tend to have higher clay contents therefore likely have a higher cation exchange capacity and more plant available moisture contents.

Further upslope, however, above the zone of colluvial materials, organic matter and clay contents tend to decrease, reaching the lowest values in the zone of inflection. Nonetheless, vertical variation of this sort is likely occur in soils developing along a toposequence, where the prevailing soil forming factor is topography, discussed in details by e.g. MEINERT, L. and BUSACCA, A. (2002), REPE, B. et al. (2017) and VRŠČAJ, B. et al. (2017). This type of spatial pattern

of soil qualities generates more fertile soils with clay-loamy textures and higher water holding and supplying capacities at foot-slope positions whereas fertility and mean moisture contents decrease with increasing elevations (BUSACCA, A. and MEINERT, L. 2003). However, in correspondence with the findings of WILKINS, D. and BUSACCA, A. (2017) obtained under similar climatic and topographic conditions to those of the Villány Hills, we also concluded that local meso- and microclimate, and in general geodiversity (STĚPIŠNIK, U. et al. 2017) may significantly influence the locality-specific terroir properties and wine quality through the spatial pattern of soil properties.
