

APPLICATION OF STACKING FOR REFRACTION TIME SECTIONS

É. SZ. KILÉNYI*

Introduction

Although the methods of multiple coverage, digital recording and data processing became quickly known in reflection seismics, their application in refraction seismics is still not generally accepted. Multicover measurements have been introduced to refraction field techniques long ago coverage however is regarded as an aid to interpretation instead of using it to increase signal to noise ratio.

In literature PERALDI (1969) was the first to adapt the methods developed in reflection seismics to refraction. In 1972 PERALDI and CLEMENT already published a processing package, constructing the refraction horizon by ray charts as a final result. All along the process however their aim seems to be the substitution of conventional interpretation by numerical methods instead of finding new ways to meet new possibilities. For the first time HIRSCHLEBER (1971) suggested multicover measurements and stacking in refraction. His solution is somewhat laboured and some delicate approximations are required at certain points, but his final aim, i.e. refraction time section seems to be surely the path of tomorrow.

Suggestive display of results is important in all branches of geophysics, but in seismics it seems to be indispensable. At the same time only attempts have been made even in well developed computerized reflection data processing to make the computer understand in form of different parameters what human eye sees. In refraction picking the change of wave form is even more important than in reflection interpretation. Display of refraction waves in the form of time section represents a new dimension in geological interpretation.

Consequently our aim is identical to that of Hirschleber, but our solutions are supposed to be simpler, easier to realize and not limited to first arrivals.

The problem

The equation of refraction time-distance curve for two layers can be given in the following form:

$$T = t_{0sp} + t_{0g} + (x/V_2) \cos \Theta \quad (1)$$

where

$$t_{0sp} = h_1 \cos \Theta (\cos i)/V_1 \quad (2)$$

and

$$t_{0g} = h_2 \cos \Theta (\cos i)/V_1 \quad (3)$$

Definition of delay time:

$$D = T - x/V_R = t_{0sp} + t_{0g} + (x/V_2) \cos \Theta - x/V_R \quad (4)$$

Where V_R is the reduction velocity.

$$\text{If } x = 0, \quad T = t_0 = t_{0sp} + t_{0g} = \text{intercept time.}$$

Some authors consider D as intercept time and t_{0g} as delay time, but sticking to conventional nomenclature we call t_{0sp} and t_{0g} the shot point delay and geophone delay respectively, keeping the expression of delay time for D .

Arrivals from different shotpoints will represent a continuous time section only if all other terms but the geophone delay are eliminated in the formula of the delay time. If this reduction is carried out by adequate precision, the covering arrivals can be stacked. Two or threefold coverage is at our disposal in every routine refraction profile. Using stacking, according to the \sqrt{n} formula a 1.4–1.7 times increase in signal to noise ratio can be achieved by no extra expenditure. Advantages of stacking concerning first arrivals are important in areas of unfavourable energy transmission and in inhabited regions, but they are always essential as to later arrivals.

Solution

The main point in the solution is to determine appropriate correction, which consists of two parts. The first part, the function of x has to be zero:

$$(x/V_2) \cos \Theta - x/V_R = 0 \quad (5)$$

$$\text{It concludes that } V_R = V_2/\cos \Theta \quad (6)$$

For possible values of Θ , $0 \leq \cos \Theta \leq 1$; so $V_R \geq V_2$.

Cos being an even function the same reduction velocity can be applied for both directions.

The second part of the correction is the determination of t_{0sp} . Hirschleber suggests a statistical method for the separation of t_{0sp} and t_{0g} . The disadvantage of his method is that it is necessary to determine the reduction velocity beforehand, but it can be done by adequate precision only after having separated the shotpoint and geophone delays respectively.

Since there are more unknowns than equations, the problem may be solved by such a shooting system where in two successive travel-time curves t_{0sp} could be determined graphically (as half of the intercept time). From the equations of two covering time-distance curves V_R can be computed:

$$T_1 = t_{0g} + t_{0sp1} + x_1/V_R$$

$$T_2 = t_{0g} + t_{0sp2} + x_2/V_R$$

and

$$V_R = \frac{x_2 - x_1}{(T_2 - T_1) - (t_{0sp2} - t_{0sp1})} \quad (7)$$

It is evident that reduction velocity is equal to the apparent velocity but corrected by the difference of shotpoint delays. As a matter of fact this term represents the dip of the horizon. If $(t_{0sp2} - t_{0sp1}) = 0$, the horizon is horizontal (except cases of very little probability), and $V_R = V_{app} = V_2$.

Having V_R , the values of t_{0g} can be easily computed and—according to our basic assumptions—are equal for both curves. If a third covering curve is given, its t_{0sp3} value can be determined from the equation of the time-distance curve supposing that t_{0g} and V_R are equal to the values as defined above. Starting from this perfectly identical point and carrying out the reduction with several possible values of V_R and stacking, the varying value of V_R can be determined by sections. As a matter of fact a method of velocity determination is attained, similar to the constant velocity scan, well proved in reflection seismics. A great advantage over reflection seismics is that errors in static correction do not influence the result of stacking.

The t_{0sp} values of newly incoming covering time-distance curves can be computed by the known value of V_R . The value t_{0sp} thus determined contains beside the real shotpoint delay time also the difference between the “antecedents” of the time-distance curves. Practically it reflects the relative relation between the reduced time values of different shotpoints.

Horizontal offset can be determined from characteristic points of straight and reversed delay time curves. Time differences however can still occur between reduced and shifted delay time curves of opposite direction because of their different “antecedents”. In case of complicated structure there is even no hope for stacking delay time curves of opposite directions. The method of stacking seems to prefer one-sided shooting systems instead of correlation systems in refraction as well as in reflection seismics. It remains an open question whether migration—to be solved in future—will allow it or not.

Concerning the case of later arrivals, reduction and stacking by a V_R determined for a given horizon will decrease the amplitude of arrivals of different velocity, because of unfavourable interference. In zones of interference properly reduced waves will gain in signal to noise ratio and will be better picked. The use of constant velocity scan on a broad scale will produce the reduction velocities of all waves of interest, while time sections for each wave can be prepared separately. The mathematical processes involved are simple, to be carried out easily by analog or digital computers.

Examples

Accuracy of velocity determination has been checked by computation on a three-fold coverage section of a Transdanubian refraction profile. Fig. 2 shows the chosen part of the time-distance graph. Shotpoint delays were determined for shotpoints

Fig. 2. Part of time distance graph of a refraction profile
 2. ábra. Egy refrakciós szelvény út—idő görbe rendszerének részlete
 Рис. 2. Деталь системы географов по профилю КМПВ

2300 and 1100 graphically. For geophone point 3450 as the point of threefold coverage with smallest x values, the reduction velocity was computed by equation (7) from the arrival times of the above two shotpoints. With the resulting velocity of 5910 m/sec, the geophone delay was computed (0.162 sec). By the above results the shotpoint delay of shotpoint 000 was determined and the reduction carried out for a whole spread of 24 geophones.

Results are listed in Table I and shown graphically on Fig. 3/a. It follows from the latter, that the reduction velocity of 5910 m/sec is satisfactory up to geophone point 3900. After this point the reduced time curves diverge. The former calculations for geophone point 4600 give a reduction velocity of 6030 m/sec. Reduction of the same data by the above velocity yields the results of Table II and Fig. 3/b. As expected conformity of the three delay time curves from 3950 to 4600 seems to be excellent. It must be noted however that errors of picking are included in these data and effective stacking may lead to even better results.

REFRAKCIÓS IDŐSZELVÉNY ELŐÁLLÍTÁSA STACKING ALKALMAZÁSÁVAL

A refrakciós mérések számítógépes feldolgozása messze elmaradt a reflexiók kiértékeléstől. Az irodalomban megjelent ilyen irányú kísérletek főleg a hagyományos kiértékelést igyekeztek megvalósítani számítógépek segítségével és nem alkalmazták a digitális technika egyéb lehetőségeit. HIRSCHLEBER (1971) javasolta először stacking alkalmazását, de megoldása nehézkes és néhol kényes közelítéseket tartalmaz. Jelen dolgozat célja refrakciós időszelvény előállítása stacking alkalmazásával, egyszerű módszerekkel.

A refrakciós késési idő definíciója:

$$D = T - x/V_R = t_{0sp} + t_{0g} + (x/V_2) \cos \Theta - x/V_R \quad (4)$$

ahol t_{0sp} és t_{0g} a robbantóponti, ill. geofonhelyi késési idők, V_R pedig a redukciós sebesség (jelölések az 1. ábrán). Ha egymást fedő sebességágakat összegeznünk akarunk, a késési idő képletében a geofonhelyi késési idő kivételével minden tagot eliminálnunk kell. A redukció két lépésből áll: először az x -től függő rész levonása, másodsor t_{0sp} és t_{0g} különválasztása. Az első rész a redukciós sebesség meghatározását jelenti, melyre a reflexiós módszerben bevált constant velocity scan módszeréhez hasonló megoldást, t_{0sp} és t_{0g} szétválasztására pedig részben grafikus, részben számítási eljárást javasolunk.

Az ismertetett módszer egyirányú lövési rendszerek alkalmazását teszi lehetővé. A stacking megvalósítása lényeges jel/zaj viszony javítást eredményezhet nemcsak az első, hanem a későbbi beérkezések tartományában is.

ПОСТРОЕНИЕ ВРЕМЕННЫХ РАЗРЕЗОВ КМПВ ПО МЕТОДУ ОГТ

Машинная обработка данных КМПВ далеко отстает от интерпретации данных МОВ. Опубликованные в литературе попытки подобного характера были направлены главным образом на использование ЭВМ для стандартной интерпретации данных, причем не были использованы дополнительные возможности цифровой техники. Впервые Хиршлебер (1971) предложил применять способ ОГТ, но предложенный им способ оказался трудоемким и содержащим delicate приближения. Целью настоящей работы является построение временных разрезов преломленных волн с применением ОГТ по простым способам.

Время задержки преломленных волн определяется соотношением:

$$D = T - x/V_R = t_{0sp} + t_{0g} + (x/V_R) \cos \Theta - x/V_R, \quad (4)$$

где t_{0sp} и t_{0g} — времена задержки в пункте взрыва и у сейсмоприемника, соответственно, а V_R — редукционная скорость (обозначения см. на рис. 1). Если хотим суммировать перекрывающиеся ветви скоростей, то в формуле времени задержки необходимо устранить все члены, за исключением времени задержки в пункте сейсмоприемника. Редукция осуществляется в два приема: сначала вычитается часть, зависящая от x , а затем разделяются величины t_{0sp} и t_{0g} . Первый прием означает определение скорости, для чего предлагается способ, подобный способу переброса скоростей, эффективно применяющемуся в методе отраженных волн, а для разделения величин t_{0sp} и t_{0g} предлагается использовать отчасти графический и отчасти вычислительный способы.

Предлагаемый метод позволяет использовать встречные системы наблюдений. Использование накопления приводит к значительному улучшению отношения сигнал/шум не только при первых вступлениях, но и в диапазоне последующих вступлений.
